(54) **Procedure for measuring a patient's impedance**

(57) The present invention relates to a procedure for measuring a patient's impedance. Based on the impedance, it is possible to monitor the patient's respiration and/or blood circulation. In the procedure, a plurality of electrodes (1a, 1b; 1d, 2; 2a) are connected to the pa-

tient and the changes in the impedance relationships between the electrodes (1a, 1b, 2) are measured. The invention makes it possible to use the same measuring conductors and measuring electrodes for impedance measurement as are used in ECG measurement.

Fig 1

EP 0 747 005 A1

Description

The present invention relates to a procedure for the measurement of impedance as defined in the preamble of claim 1.

An impedance method is used to measure a patient's respiration and blood circulation, such as cardiac stroke volume, cardiac output, cardiac contractility indices, thoracic fluid content, deep vein thrombosis, peripheral blood flow and arterial occlusive disease.

Impedance respiration measurement, i.e. respiration measurement by the aid of a variable impedance, is based on the measurement of changes in electric conductivity in the chest. Electric conductivity decreases during inhalation as air flows into the lungs, air having a low electric conductivity, and increases during exhalation as air is discharged from the lungs.

The measurement is generally performed using a high-frequency constant current as measuring current, so that the impedance of the chest can be calculated from the voltage set up across it. In this case, the chest impedance is mainly resistive, with a reactive component of only about 15%. Measured with a 100 kHz signal, the resistance of the chest generally has a magnitude of about 20-60 ohm. Respiration only causes a change of approx. 0.1 - 1 ohm in it, because most of the measuring current does not flow through the highly resistive lung tissue but through the muscles and the back.

In addition, the measurement is disturbed by the stray capacitances of the cables and amplifier, although these only have a minor significance because the voltage generated across them is in different phase relative to the voltage generated by the resistive component of the impedance of the chest.

A high-frequency measuring current is used because the impedance of the electrodes decreases with increasing frequency. The skin-electrode impedance decreases to one hundredth when the measurement signal is increased from a low frequency to 100 kHz. In practice, the upper limit for the measuring signal frequency is about 100 kHz, because at higher frequencies too much of the measuring current begins to flow through stray capacitances. The measuring frequencies used are generally in the range of 10...100 kHz.

In impedance measurements previously known, two or more electrodes are used. When the measurement is performed using two electrodes, the measuring current has to be supplied via the same electrodes as are used for the measurement itself. This results in a measurement error, because the current density is larger in the vicinity of the current supply electrodes, and the impedance changes occurring in the tissue near the current supply electrodes appear larger in relation to those occurring in the rest of the tissue. Moreover, the non-linearity of the current density in the tissue causes error in the measurement result.

In practical monitoring, however, the biggest drawback with two-electrode measurement is that the imped-

ances of the electrodes and measuring cables are summed with the chest impedance, with the result that the small change in chest impedance caused by respiration easily gets lost in the total impedance.

To correct the measurement errors referred to above, measuring procedures involving four or more electrodes have been developed. In a four-electrode procedure, the current is supplied to two outer electrodes and the measurement is performed with two inner electrodes. When the measuring amplifier has a high input impedance, the current flowing through the measuring electrodes, which causes a measurement error, is small. Besides, the impedances of the current supply cables and electrodes are not summed with the impedance to be measured. In addition, the measurement area can be located at a larger distance from the current supply electrodes, in which case the magnitude of the current density in the tissue in the area between the measuring electrodes is roughly constant. Moreover, the impedance changes in the area between the measuring electrodes appear larger in relation to the changes in other areas, making it possible to define the measurement area more precisely. In addition, the measurement area extends deeper into the tissue.

By using guard electrodes in addition, the error caused by the non-linearity of the current density can be reduced. By further increasing the number of electrodes used, the measurement area can be focused better and it is even possible to compute an impedance tomogram by means of a computer.

Since impedance respiration measurement in patient monitoring is generally performed simultaneously with ECG measurement using the ECG cable as measuring cable, two-point measurement is generally used, because the monitors usually have three-wire ECG cables. This means that the above-described problems associated with two-point measurement cause disturbances in the measurement.

The object of the present invention is to eliminate the problems described above.

A specific object of the present invention is to produce a new type of procedure for monitoring a patient's respiration.

A further object of the present invention is to produce a simple and reliable procedure for monitoring a patient's respiration, allowing respiration monitoring to be performed using the same measuring cables and electrodes as in ECG measurement.

As for the features characteristic of the present invention, reference is made to the claims.

In the procedure of invention for measuring a patient's impedance, at least two, preferably three electrodes are connected to the patient. It is also possible to use more than three electrodes. According to the invention, the patient's respiration or blood circulation is monitored by measuring the changes in the impedance relationships between the electrodes. The essential feature of the procedure of the invention is that one or pref-

erably more than one impedance formed in the patient between electrode pairs is/are measured, one of said electrodes being a grounding electrode, on which the measurement is performed. In a preferred case, the change in the relation between the measured impedances is determined.

The procedure of the invention has the advantage that the measurement of a patient's respiration can be performed using the same measuring cables and electrodes as are used for ECG measurement.

A further advantage of the procedure of the invention is that equal cable impedances and equal electrode impedances as well as equal tissue impedances cancel each other, so the carrier of the signal to be measured is small and the relative modulation produced in the carrier by respiration is therefore larger and thus easier to measure than in prior-art two-point measurement.

Furthermore, the procedure of the invention eliminates the earlier problems resulting from the measuring cable impedances being summed with the impedance to be measured, and no separate low-impedance respiration measurement cable is needed because the impedances cancel each other, but instead the normal ECG cable supplied by the monitor manufacturer can be used.

An additional advantage of the present invention as compared with prior art is that the procedure of the invention allows the impedance change to be determined more accurately and more reliably than in the earlier two-point measurement.

In an embodiment of the procedure of the invention, the electrodes are arranged asymmetrically relative to the lungs, so that the impedances between the electrodes will be affected differently by the alveolar air in the lungs. In addition, a measuring signal is fed into the patient through one of the electrodes and the modulation of the measuring signal caused by the inter-electrode impedances is determined. From the modulation, it is possible to conclude the change in the impedance relationship and further that air is flowing into or out of the patient's lungs, air having a poor electric conductivity.

In a preferred embodiment, a measuring signal is supplied via two electrodes, one of the electrodes is grounded with a grounding impedance, which may consist of a resistor, coil, capacitor or a combination of these, and the voltage appearing across the grounding impedance, the current flowing through the grounding impedance or the phase of the voltage or current is measured. The measured voltage is further compared with the measuring signal to determine its modulation.

The measuring signal can also be supplied via the grounding electrode.

In a preferred embodiment, the voltage of an individual electrode or the voltage difference between the electrodes can be measured, and, based on this measurement, the change in the impedance relationships between the electrodes can be determined.

In an embodiment of the present invention, a plurality of electrodes are connected to the patient. In this case, it is also possible to measure the relative change in the impedances appearing in the area between the electrodes in relation to each other. The measuring signal is preferably an a.c. signal having a frequency of about 10 - 100 kHz, preferably about 30 kHz. The measuring signal may be a voltage signal or a current signal.

In the following, the invention is described by the aid of embodiment examples by referring to the attached drawing, in which

Fig. 1 illustrates the principle of implementation of a procedure as provided by the invention; and Fig. 2 presents a diagram representing an embodiment of the procedure of the invention. Fig. 3 presents a diagram representing an embodiment of the procedure of the invention which is used for monitoring a patient's blood circulation.

Referring to Fig. 1 and 2, the procedure of the present invention is applied to the measurement of a patient's respiration as follows. Electrodes 1a, 1b and electrode 2 are connected to the patient, preferably in the region of the lungs and asymmetrically relative to the lungs. As the respiration is monitored using the same measuring cables and electrodes as in ECG measurement, electrodes 1a and 1b correspond to the active electrodes in ECG measurement and electrode 2 to the neutral electrode in ECG measurement. Fig. 1 also presents the patient impedances Z_{p1} and Z_{p2} appearing between the electrodes. Between active electrode 1a and the neutral electrode 2, patient impedance Z_{p1} appears, and between active electrode 1b and the neutral electrode 2, patient impedance Z_{p2} appears.

Through the active electrodes 1a, 1b, a measuring signal in opposite phase is supplied, which may be e.g. a ± 12 V voltage signal having a frequency of 30 kHz. In the embodiment in Fig. 2, the measuring signal is supplied from a signal generator 5 directly to electrode 1a and via an inverter 6 to electrode 1b. When the body impedance remains unchanged and the impedances Z_1 and Z_2 on each side of the vertical broken line in Fig. 2 are approximately equal, the voltage across the grounding impedance 3, measured by means of amplifier 4, is approximately zero, because the voltages in opposite phase cancel each other. If this is not the case, the impedances Z_1 and Z_2 can be matched e.g. as follows. Referring to Fig. 2, matching can be achieved in the circuit in Fig. 2 by supplying an asymmetric bipolar measuring signal, in other words, by supplying one of the electrodes 1a, 1b with a smaller measuring signal than the other. In practice, the matching is performed e.g. by adjusting the gain of the amplifier acting as an inverter by means of a gain control circuit 7. The control circuit 7 is controlled by a synchronised demodulator 8 connected to the output of the measuring amplifier 4. The purpose of the matching is to balance the unchangeable compo-

nents of the impedances so that the carrier produced by them at the measuring point is zero, permitting the relative modulation of the carrier of the measuring signal to be seen considerably more clearly, due to the change in the impedance relationship, than in prior-art solutions.

When the patient is breathing, he/she inhales air, which has a low electric conductivity, and if the active electrodes 1a, 1b have been suitably connected to the patient, the air has a different effect on impedance Z_{p1} than on impedance Z_{p2} , thus having an effect on the impedance relationship $Z1/Z2$. The impedance change further affects the voltage across the grounding impedance 3, and this voltage is compared with the supply signal. Based on this comparison, it is possible to establish the change in the impedance relationship and whether the patient is breathing or not.

Referring further to Fig. 1 and 2, possible embodiments of the invention are presented as a summary. The measuring signal generator may be either a current generator or a voltage generator, in other words, the measuring signal fed into the patient may be either a current signal or a voltage signal. Further, the measuring signal can be supplied to the electrodes either in unipolar or in bipolar form, i.e. either in opposite phase or in phase. In addition, the measuring signal can be supplied from one or more electrodes, and more than three electrodes can be used. Moreover, the measuring signal can be supplied via a resistor, capacitor, coil, transformer or a combination of these. The essential point in the procedure of the invention is that, by means of the measuring signal, the change in the relationship between impedances $Z1$ and $Z2$ is determined, said change being proportional to changes in the amount of alveolar air in the patient's lungs.

Let it be further noted that the procedure of the invention can also be implemented using two electrodes so that the signal is supplied via one electrode while the other electrode is grounded with a grounding impedance. In this case, the voltage across the grounding impedance, the current flowing through the grounding impedance or the phase of the voltage or current is measured and compared with the measuring signal, whereupon the change in the patient impedance between the electrodes can be determined on the basis of this comparison.

Referring to Fig. 3, in the following is a description of the use of impedance measurement as provided by the invention for the monitoring of a patient's blood circulation, especially for determining the pulse volume curve based on the fact that blood-filled tissue has a lower impedance. In Fig. 3, blood circulation in a patient's calf vein is being monitored. Fig. 3 shows part of the patient's leg 9, with the patient sitting e.g. on the edge of a bed. In Fig. 3, placed around the calf is a blood pressure cuff 10, which can be set tight around the calf by pumping air into it. The air is pumped into the cuff 10 by means of a pumping device 12 connected to it. Connected to the patient is an electrode 1d and a grounding elec-

trode 2a, a measuring signal being supplied from an a.c. generator 11 via electrode 1d. As for the measurement of the impedance, reference is made to the description presented above by referring to Fig. 1 and 2.

This method aims at measuring venous reflux. When the valves in the veins are in good condition, there is less reflux. When air is pumped into the cuff, the blood flows away from the veins as the cuff exerts a pressure on them. When the cuff is deflated, the veins are refilled with blood. If the valves in the veins leak, then the veins are refilled more quickly and therefore the impedance change is faster than in the case of healthy valves.

The invention is not limited to the examples of its embodiments described above, but instead many variations are possible in the scope of the inventive idea defined by the claims.

Claims

1. Procedure for measuring a patient's impedance, in which procedure a plurality of electrodes (1a, 1b; 1d, 2; 2a) are connected to the patient and in which the patient's impedance is measured from changes in the relationships of an impedance or impedances between the electrodes, **characterized** in that
 - a measuring signal is supplied via electrodes (1a, 1b, 1d or 2; 2a);
 - an electrode (2; 2a) is grounded with a grounding impedance (3; 3a); and
 - the voltage across the grounding impedance, the current flowing through the grounding impedance and/or the phase of said voltage or current is measured, this measured quantity being proportional to the patient impedance.
2. Procedure as defined in claim 1, **characterized** in that the measured voltage, current or phase is compared with the measuring signal to determine the modulation of the measuring signal, said modulation being proportional to the relationship of the impedances between the electrodes and the neutral electrode or to the impedance between the electrodes and the neutral electrode.
3. Procedure as defined in claim 1 or 2, **characterized** in that the impedance measurement is used as a basis in monitoring the patient's respiration.
4. Procedure as defined in claim 1 or 2, **characterized** in that the impedance measurement is used as a basis in monitoring the patient's blood circulation, such as cardiac stroke volume, cardiac output, cardiac contractility indices, thoracic fluid content, deep vein thrombosis, peripheral blood flow and arterial occlusive disease.

5. Procedure as defined in any one of claims 1 - 4, **characterized** in that
- the electrodes are so arranged relative to the patient's lungs and/or blood circulation that respiration and/or blood circulation will cause changes in the impedance relationship to be measured; 5
 - a measuring signal is supplied into the patient through one of the electrodes (1a, 1b; 1c, 1d, 2; 2a); and 10
 - the modulation of the measuring signal effected by the impedances between electrodes (1a, 1b; 1c, 1d) and electrode (2; 2a) is determined. 15
6. Procedure as defined in any one of claims 1 - 5, **characterized** in that the asymmetry between the basic impedances to be measured is compensated by means of a voltage asymmetry of the measuring signal supplied, permitting the change in the asymmetry of the impedances to be more clearly distinguished. 20
7. Procedure as defined in any one of the preceding claims 1 - 6, **characterized** in that the asymmetry between the basic impedances to be measured is compensated by means of a matching impedance. 25
8. Procedure as defined in any one of the preceding claims 1 - 7, **characterized** in that the measuring signal is supplied via electrodes (1a, 1b; 1d) in opposite phase. 30
9. Procedure as defined in claim 3, **characterized** in that the measuring signal is supplied via one electrode (1a, 1b; 1d, 2; 2a). 35
10. Procedure as defined in any one of the preceding claims 1 - 9, **characterized** in that 40
- the voltage of electrodes (1a, 1b; 1d) and electrode (2; 2a) and/or the corresponding voltage difference is measured; and
 - the measured voltage and/or the corresponding voltage difference are/is compared with the measuring signal in order to determine the modulation of the measuring signal, said modulation being proportional to the relationship of the impedances between the electrodes. 45
11. Procedure as defined in any one of the preceding claims 1 - 10, **characterized** in that the measuring signal is an a.c. signal having a frequency of about 10 - 100 kHz, preferably about 30 kHz. 50
12. Procedure as defined in claim 10, **characterized** in that the measuring signal is a voltage signal. 55
13. Procedure as defined in claim 10, **characterized** in that the measuring signal is a current signal.
